

## 6.100L Recitation 9

### Reminders

- MQ 9 on Monday 11/21

### Review from the last 2 weeks...

#### Object Orientation Programming (OOP)

- Objects allow you to store data in python
- Everything in python is an object
- Class defines a type of object
  - so far in class we have seen the following built-in classes: int, float, string, list, tuples, dictionaries
- An object is an instance of its class
  - for example: 3, "hello", [1,2,3] are all instances of a class
- Advantages of OOP:
  - Allows you to bundle data into packages
  - Reduces complexity of your code, making it easy to reuse code
  - Allows you to implement & test behavior of each class separately

### Classes

- a way to create your own data type using the built-in data types as building blocks
  - Real life examples: Elevator, employee, queue at store, stack of pancakes...
- attributes are data & procedures that belong to the class
  - Data attributes: objects that make up the class
  - Methods/procedural attributes: functions that only work with this class
- self:
  - Refers to the instance the method is called on
  - Always the 1st argument when defining a method
  - Not used outside the class definition
- Creating a class:
  1. Define class name

```
class Coordinate(object):  
    #define attributes here
```

*class definition* (pointing to `class`)  
*name/type* (pointing to `Coordinate`)  
*class parent* (pointing to `object`)

#### 2. Define class attributes

- a. Define how to create an instance of a class using the `__init__` method

```
class Coordinate(object):  
    def __init__(self, x, y):  
        self.x = x  
        self.y = y
```

*special method to create an instance — is double underscore* (pointing to `__init__`)  
*what data initializes a Coordinate object* (pointing to `x, y`)  
*two data attributes for every Coordinate object* (pointing to `self.x` and `self.y`)  
*parameter to refer to an instance of the class* (pointing to `self`)

- b. Define other methods, these do not need to start with `__`

These methods only work for this class.

```
class Coordinate(object):  
    def __init__(self, x, y):  
        self.x = x  
        self.y = y  
    def distance(self, other):  
        x_diff_sq = (self.x-other.x)**2  
        y_diff_sq = (self.y-other.y)**2  
        return (x_diff_sq + y_diff_sq)**0.5
```

*use it to refer to any instance*  
*another parameter to method*  
*dot notation to access data*

- Using a class:
- First create a new instance of the class
  - # Using the example Coordinate class above
  - c1 = Coordinate(1,1)
  - c2 = Coordinate(2,1)
- Carry out operations on the instances, using class methods
  - c1.distance(c2)
- In order to be able to call print on an instance of your class you need to define the `__str__` function.
  - there are a few more special operators ( `__len__`, `__eq__` etc... → look at lecture slides for details on these)
- You can use `isinstance()` to check if an instance is an object of a class.
- In general the class defines the representation and methods common across all instances of the class; whereas an object is a SPECIFIC instance of the class
- In general you want to keep your internal representation of your class hidden, to prevent adversarial attacks and bugs.
  - the internal representation refers to what is in your `__init__` method
- class variables: shared across all members of a class
  - defined outside of the `__init__` method

### Getter and Setter Methods:

- Getter and setters should be used outside of classes to access data attributes.
- It's better style to access attributes this way, makes code easier to maintain and

helps prevent bugs

### **Inheritance & Hierarchies:**

Why use inheritance?

- Allows you to extend a class with new/different capabilities.
- Reuse code
- Commonalities are explicit in the parent class, differences explicit in the subclass

Structure & how it works:

- You create an inheritance relationship between two classes by defining what goes into the parameter in the class definition.

- Define parent class

```
class CreditCard(object):
```

Define child class:

```
class RewardCard(CreditCard):
```

The child class inherits all the methods from the parent class.

- We can define new methods in the child class to extend behaviour
- We can redefine methods defined in the parent class to modify behaviour
- When you call a method on an instance of a class: the interpreter tries to find the method at the level of a class and then checks the parent.
  - This means that if two methods with the same name are defined, the method in the child class takes precedence.
